## Abstract

Weighting judges by their reported confidence is often described as the optimal way to combine binary judgments, but the rule is only conditionally optimal: correlated errors change the optimal weights, miscalibrated competence inputs degrade them, and estimated weights routinely lose to the simple average. We ask the finite-sample question an aggregator can act on: given the number of judges, the confidence–accuracy slope, and the within-item error correlation, when does confidence weighting (CW) lose to equal weighting (EW), and is partial shrinking better than either? We specify the gap, map its boundary in a preregistered simulation, and test it on 76 datasets from the Confidence Database (1,641,000 trials). The simulation has a boundary: CW helps both objectives only when confidence is well calibrated, and overconfidence reverses the graded effect. In the data the two objectives diverge. On the preregistered crowd-decision measure CW is a small but reliable improvement (+0.004, 95% CI [0.0003, 0.0083]; +0.007 on items the crowd does not already decide), and in a held-out item test it reaches 0.938 accuracy against 0.926 for equal weighting. On the exploratory graded measure, which predicts a held-out judge's correctness rather than the item's truth, CW is slightly worse (Brier improvement −0.0006, negative in 91% of datasets). Neither the calibration slope nor the within-item error correlation moderates either effect, and an estimated shrinkage weight beats equal weighting in only 24% of datasets. Confidence weighting buys a small decision gain and a small judge-prediction loss; the two objectives should not be conflated.

**Keywords:** wisdom of crowds; confidence; aggregation; calibration; correlated error; shrinkage

## 1. Introduction

Combining the judgments of several people usually beats asking one. The advantage comes from cancelling idiosyncratic error: if judges are on average better than chance and wrong for different reasons, the simple majority grows more accurate as judges are added (Condorcet, 1785/1994). This result, and the conditions under which it holds (Berend & Paroush, 1998), underpins practical advice to poll, average, or vote rather than to defer to a single expert.

A natural refinement is to weight judges by how confident they are. If a judge's reported confidence is the probability she is right, and errors are independent, then weighting votes by the log odds of correctness, which confidence is taken to track, is the optimal way to recover a binary truth (Grofman, 1978; Nitzan & Paroush, 1982; Ben-Yashar & Nitzan, 1997). The intuition is widespread: a confident judge should count for more than a hesitant one. It also sits within a large literature on combining opinions. People appreciate averaging less than they should (Larrick & Soll, 2006; Soll & Larrick, 2009); identifying expertise improves crowd accuracy (Budescu & Chen, 2015); pooling independent judgments boosts medical diagnosis (Kurvers et al., 2016); a small select crowd can match a large one (Mannes et al., 2014); and how information is shared between judges changes what aggregation achieves (Palley & Soll, 2019). Metacognitive variants, such as asking what others will answer, extend the same goal (Prelec et al., 2017).

Three literatures make the optimality conditional in ways worth stating plainly. First, committee theory shows that the optimal weights depend on the structure of shared error. When voters' judgments are correlated, equal or competence-proportional weighting is not generally optimal (Shapley & Grofman, 1984; Ladha, 1995; Kaniovski, 2010), and additional judges stop helping once their errors move together (Hogarth, 1978; Einhorn et al., 1977). Second, the forecast-combination literature shows that estimated optimal weights routinely fail to beat the simple average, because estimating many weights from few observations adds variance (Smith & Wallis, 2009; Claeskens et al., 2016). Huang, Broomell and Golman (2024) formalise this as a test of whether weighting "reliably improves collective accuracy or just adds noise". Third, when the

weights come from a distorted competence signal rather than true competence, the optimal rule degrades (Baharad & Ben-Yashar, 2009). Reported confidence is exactly such a signal, and it is only weakly related to accuracy: pooling 145 datasets, Jin, Verhaeghen and Rahnev (2022) found a positive but modest confidence–accuracy correlation. Empirically, confidence-weighted majority voting can beat unweighted majority voting (Saha Roy et al., 2021; Meyen et al., 2021), and confidence-based rules can make crowds more efficient (Berger et al., 2025), but people themselves weight votes more equally than the optimal confidence rule prescribes (Meyen et al., 2021).

What remains underexamined is the boundary in the terms a crowd aggregator actually has: the number of judges, the strength of the confidence–accuracy relationship, and the correlation of errors within an item. Existing results are stated for abstract competences or for estimated weights; they are not written so that an analyst who knows her crowd size and the calibration of her confidence measure can say whether weighting will help. Nor has the size of the CW advantage been mapped across many real judgment datasets, so its typical magnitude is unknown. The practical question is not whether confidence weighting can help, which is settled, but how large the gap between CW and EW usually is, and when the sign turns.

We address this in three steps, and we report the results in full whichever way they come out. First, we write the expected gap between CW and EW as a function of the confidence–accuracy calibration slope, the within-item error correlation, and confidence dispersion, in the finite-sample regime of a handful of judges per item. Second, we map the boundary of the harmful region in a preregistered simulation where confidence is generated with a tunable amount of overconfidence, and derive the shrinkage between CW and EW that is accuracy-optimal. Third, we estimate where real judgment data sit, using 76 datasets from the Confidence Database (Rahnev et al., 2020), and test whether the observed pattern follows the theoretical inputs.

This is a Theory Article with an empirical test. We do not claim that confidence weighting can hurt, that correlated error changes optimal weights, or that confidence-weighted voting sometimes beats majority: those are established (Baharad & Ben-Yashar, 2009; Huang et al., 2024; Meyen et al., 2021; Shapley & Grofman, 1984). The contributions are the psychometric parametrisation of the gap, the simulated boundary, the estimated base rate of the harmful region, and a negative result: the simple account does not reproduce the data. Our preregistration, including the analysis plan and the criteria for each outcome, was committed before the outcome variables were analysed; it and every deviation are in the project repository.

## 2. A finite-sample account

### 2.1 Setup

Consider an item $i$ with a binary truth. Judge $j$ reports a binary judgment and a confidence $c_{ji} \in [0, 1]$. Encode the judgment by its correctness, $v_{ji} = +1$ if the judge is right on that item and $-1$ if wrong. The two aggregation rules are the equal-weighted (EW) mean and the confidence-weighted (CW) mean:

$$\bar{x}_i = \frac{1}{m} \sum_{j=1}^{m} v_{ji}, \qquad \hat{x}_i = \frac{\sum_{j=1}^{m} c_{ji}\, v_{ji}}{\sum_{j=1}^{m} c_{ji}},$$

where $m$ is the number of judges on the item. The crowd decision is correct when the estimate is positive. This encoding uses recorded correctness directly, without reconstructing the truth from responses, and it makes the two rules differ only in their weights.

### 2.2 Bias, variance and the gap

Write the crowd estimate as a weighted mean with weights $w_j$ (all $1/m$ for EW, $c_j / \sum c$ for CW). Conditional on the item, its variance is $\mathrm{Var}(\hat{x}_i) = \sum_j w_j^2 \,\mathrm{Var}(v_{ji}) + \sum_{j \neq k} w_j w_k \,\mathrm{Cov}(v_{ji}, v_{ki})$. With $m$ judges whose residual variances are comparable, the first term falls as $\sum_j w_j^2$, so a more unequal weighting raises the variance at fixed $m$; CW therefore pays a variance cost the EW estimate does not. Its mean, $\sum_j w_j \, E[v_{ji}]$, is higher when the weights concentrate on judges who are more likely to be right. The gap between the two rules is the difference between this weighting gain and the variance cost.

Three quantities govern the trade-off. The **calibration slope** $\beta$, from a regression of correctness on normalised confidence, sets how sharply the weights separate good judges from bad. **Confidence dispersion** sets how unequal the weights are, and hence the size of the variance cost. The **within-item error correlation** $\rho$ is external to the judge: when errors are shared, an item that is hard for one judge is hard for all, the covariance term is large, and reweighting within the item shuffles a quantity whose average is already set by the shared component.

Two limits are instructive and give the sign condition. If confidence is perfectly calibrated and errors are independent ($\beta$ large, $\rho = 0$), CW approaches the optimal rule, its weighting gain dominates the variance cost, and the gap is positive, growing with $m$ as the estimate converges on the item's expected correctness. If confidence carries no information about correctness within the item, CW is a weighted mean with weights independent of $v_{ji}$; it is then unbiased but strictly noisier than EW, so the gap is negative and shrinks towards zero as $m$ grows and the weights average out. In the finite-sample regime, the gap is negative whenever the weighting gain, which is proportional to the within-item covariance of $c_{ji}$ with $v_{ji}$, falls short of the variance cost, which grows with the dispersion of $c_{ji}$ and falls with $m$. The empirically relevant case lies between these limits, and the sign depends on which term dominates at the given $m$.

The ingredients here are the ones already used in the correlated-votes and forecast-combination literatures. Baharad and Ben-Yashar (2009) study how a distorted competence signal degrades the optimal weighted-majority rule in the abstract committee setting; we instantiate that signal as reported confidence, add confidence dispersion as an explicit term, and give the finite-sample rather than the asymptotic form. The contribution is to write the gap in the psychological coordinates an aggregator can estimate, and to attach a simulation and a base rate to it. Because the finite-sample variances depend on the full confidence distribution, we do not claim a closed form for all cases; we give the sign condition above and solve the gap numerically where the closed form is not tractable. The framework also yields a prescriptive quantity. Define the shrinkage estimator

$$x_i^{\lambda} = (1 - \lambda)\, \bar{x}_i + \lambda\, \hat{x}_i,$$

with $\lambda = 0$ reproducing EW and $\lambda = 1$ reproducing CW. If the weighting gain and the variance cost trade off, the accuracy-optimal $\lambda^{\star}$ will often lie strictly between the two, and shrinking towards equal weights is better than either extreme. Whether an interior optimum exists, and where, is a question for the simulation.

## 3. Simulation

### 3.1 Model and method

We simulated judgments and confidence for many independent items. Each item $i$ has a latent position $\delta_i \sim N(0,1)$ that fixes its truth $T_i = \text{sign}(\delta_i)$; a shared error $u_i \sim N(0, \tau^2)$ common to all judges on the item; a persistent judge ability $a_j \sim N(0, 0.7^2)$; a persistent judge overconfidence trait $o_j \sim N(0,1)$, independent of ability; and private noise $\varepsilon_{ji} \sim N(0,1)$. The judge's signal is $s_{ji} = \delta_i + u_i + a_j + \varepsilon_{ji}$, and the judgment is correct when $\text{sign}(s_{ji}) = T_i$. Confidence reflects the strength of the judge's own evidence and the overconfidence trait, not the truth,

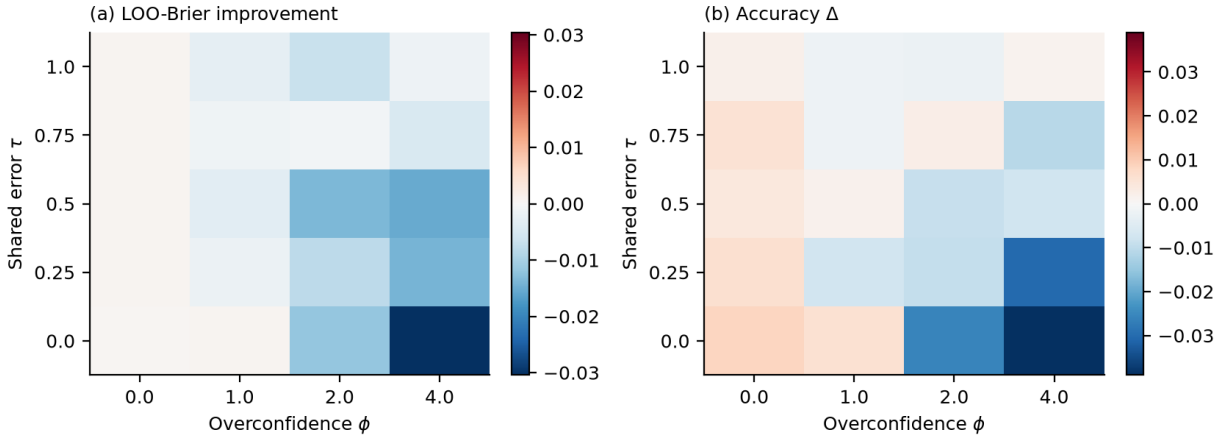

$$c_{ji} = \text{sigmoid}(\gamma\, |s_{ji}| + \phi\, o_j) + \nu_{ji},$$

with $\nu_{ji} \sim N(0, \omega^2)$, min–max normalised as in the empirical analysis. The parameter $\gamma$ sets how sharply confidence tracks correctness, $\phi$ is overconfidence (confidence not diagnostic of accuracy), and $\tau$ drives the within-item error correlation $\rho$. We swept $\tau \in \{0, 0.25, 0.5, 0.75, 1.0\}$, $\phi \in \{0, 1, 2, 4\}$, $\gamma \in \{0.3, 0.6, 1.0\}$ and $\omega \in \{0.05, 0.1\}$, with 40,000 items per cell and group sizes $m \in \{3, 4, 5, 7, 9, 13, 17, 25, 41, 65\}$. For each cell we recorded the sign-accuracy gap $\Delta(m)$, the leave-one-judge-out Brier improvement of CW over EW, and the accuracy-optimal shrinkage $\lambda^{\star}$.

The **failure condition** set in advance was that the simulation must reproduce either the qualitative published result that real groups weight more equally than the confidence-optimal rule (Meyen et al., 2021) or the sign pattern of the empirical gap. A model that reproduces neither is rejected.

### 3.2 Results

The sign-accuracy gap has a clear boundary (Figure 2b). Of the 120 simulated cells, 86 (72%) show a negative gap at one or more group sizes, and the sign is governed by overconfidence: at $\gamma = 0.3$ and $\tau = 0$ the mean gap is $+0.008$ when confidence is well calibrated ($\phi = 0$) and $-0.039$ when it is not ($\phi = 4$). Higher shared error compresses the gap towards zero but does not reverse it.

The gap does not increase monotonically with group size as the finite-sample reading predicts: 275 of 1,080 steps exceed the Monte-Carlo tolerance in the decreasing direction, so H2 is not supported and the relation is non-monotone in a substantial minority of cells.

The graded estimate shows the same boundary more sharply (Figure 2a). CW improves the leave-one-judge-out Brier score when confidence is well calibrated (mean $+0.0006$ at $\phi = 0$, $\tau = 0$) and degrades it once overconfidence is present ($-0.012$ at $\phi = 2$, $-0.030$ at $\phi = 4$). Across the grid, 41 of 120 cells have a positive mean Brier improvement and 79 negative.

An interior optimum is common in the simulation, though it is an oracle result. In 117 of the 120 cells the accuracy-optimal shrinkage $\lambda^\star$, chosen with knowledge of the population parameters, lies strictly between 0 and 1 for at least one group size (Figure 3). The optimal weight on confidence falls as overconfidence rises, reaching zero when confidence is uninformative. Whether an estimated shrinkage weight helps in practice is a separate question, tested in Section 4.

The simulation satisfies the failure condition in the sense that it has an adverse region consistent in spirit with Meyen et al. (2021), but Section 4 shows that its specific predictions do not match the data, which the preregistration treats as a failure of the account rather than the simulation.

## 4. Empirical test across 76 datasets

### 4.1 Data and method

We used the Confidence Database (Rahnev et al., 2020; OSF `s46pr`, CC0), a collection of trial-level datasets in which participants make a judgment and rate their confidence. Of 180 per-study files, 76 met the structural inclusion rules fixed before analysis: an explicit correctness column, a stimulus identifier, at least eight participants, non-constant confidence, at least two items judged by three or more participants, and enough judges per item to support the preregistered group sizes. Together these contain 1,641,000 analysed trials. Median calibration slope was 0.52 (on standardised confidence), median within-item error correlation 0.11, and the median item was judged by 33 participants.

An **item** is a shared cell, defined as the stimulus value together with any of a fixed list of design columns

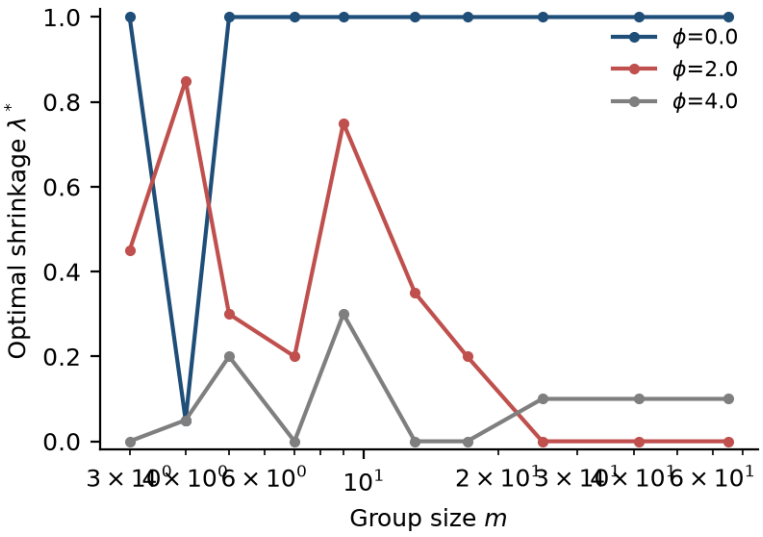

Figure 1: **Figure 3.** Accuracy-optimal shrinkage lambda* between equal weighting (0) and confidence weighting (1) against group size, for three levels of overconfidence. An interior optimum is the rule across the grid.

present in the dataset (for example contrast or coherence). A judge's **vote** in an item is the mean of $2 \times \text{correct} - 1$ over her trials in it, and her **confidence** is the mean rating, min–max normalised within the dataset. This uses the recorded correctness directly and does not require reconstructing a per-item truth.

We computed two quantities. The **sign-accuracy gap** is the difference in the proportion of items on which the crowd decision is correct, CW minus EW, estimated at group sizes $m \in \{3, 5, 7, 9, 13, 17, 25, 40\}$ not exceeding the dataset's median judges per item, by drawing 2,000 random subsets of distinct judges per item. The **leave-one-judge-out (LOO) Brier improvement** is, for each item and each target judge, the Brier score of the other judges' EW estimate minus that of the CW estimate; positive means confidence weighting predicted the target judge's correctness better. This is a graded version of the aggregation question that predicts a held-out judge rather than the item's truth, and it was added after the sign-accuracy estimand proved insensitive; the preregistered sign-accuracy results are reported in full alongside it.

We estimate per dataset the calibration slope $\beta$ (ridge-penalised logistic regression of correctness on standardised confidence, robust to separation) and the within-item error correlation $\rho$ (one-way random-effects ICC on the judge-item table), then relate the estimated effect to those inputs with an OLS regression using robust standard errors.

### 4.2 Results

The two objectives diverge, and the divergence is the central empirical finding. On the preregistered crowd-decision measure, confidence weighting is a small but reliable improvement: the sign-accuracy gap is +0.004 (95% CI [0.0003, 0.0083]), positive in 35% of datasets, exactly zero in 20%, and negative in 45%. The small size is partly a ceiling: equal-weighted crowd accuracy is already 0.93 at three judges and 0.98 at forty, so most items are decided correctly under either rule and the room for improvement is bounded. Restricting to items the crowd does not already decide (where the mean vote is not decisive, available in 56 datasets) the gap grows to +0.007, so the effect is concentrated where weighting can change a decision. In a held-out test that estimates the shrinkage weight on one half of the items and scores it on the other (50 datasets), confidence weighting reached 0.938 accuracy against 0.926 for equal weighting, and the estimated-shrinkage rule 0.933, beating equal weighting in only 24% of datasets. On the decision objective, in short, confidence weighting helps slightly and shrinking does not reliably improve on it.

The graded measure points the other way. The leave-one-judge-out Brier improvement of CW over EW is −0.0006 (95% CI [−0.0008, −0.0003]) and is negative in 91% of datasets, and it is negative in 79% at a group size of seven. Clipping confidence to its 5th–95th percentile makes the loss larger, not smaller (−0.0007, negative in 97%). This measure predicts a held-out judge's correctness, not the item's truth, so it is not a second test of the decision question; it is a different objective, and the two objectives come apart here, as the theory allows when errors are shared.

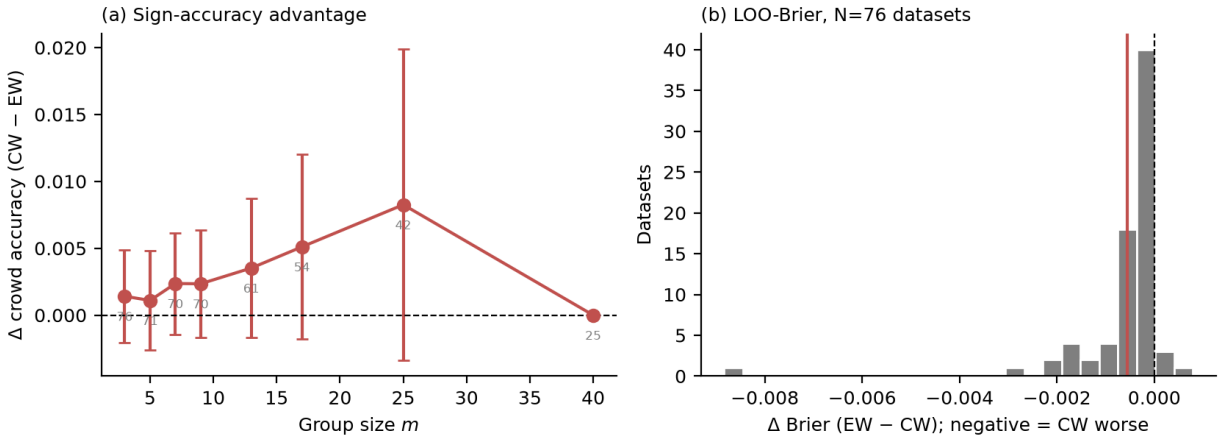

Figure 2: **Figure 1.** Confidence weighting versus equal weighting in 76 Confidence Database datasets. (a) The sign-accuracy advantage of CW over EW as a function of group size; points are means across datasets with 95% confidence intervals, the dashed line is zero, and the small grey numbers are the number of datasets contributing at each group size. (b) Distribution of the leave-one-judge-out Brier improvement of CW over EW across datasets; the red line marks the mean, and negative values mean CW is worse.

The predicted moderation does not appear on either measure. Regressing the sign-accuracy gap on the calibration slope and the within-item error correlation, neither coefficient is distinguishable from zero (calibration slope +0.015, SE 0.014; error correlation +0.010, SE 0.007). The same holds for the graded measure and for a within-item decomposition of the calibration slope, which isolates the within-item signal the theory needs from the between-judge association (within-item slope +0.045, SE 0.037; error correlation +0.010, SE 0.007). H5, which predicted that flatter calibration and higher error correlation would make CW worse, is not supported. This is an acceptance of the null, and the tests have limited power: the minimum effect detectable at 80% power is about 0.040 per unit of the calibration slope and 0.018 per unit of the error correlation, so an effect smaller than that would not have been seen. The honest statement is that no moderation of the predicted size was detected, not that none exists.

Finally, the calibrated simulation does not reproduce the data under the mapping we used. Matching each dataset to the nearest simulated cell in standardised (calibration, error-correlation) space, and comparing at a common group size of seven, the simulation matched the sign of the sign-accuracy gap for 25 of 70 datasets (36%, against a 30% baseline of always predicting a positive effect) and the sign of the Brier improvement for 27 of 70 (39%, against a 79% baseline of always predicting a negative effect). The mapping is crude, matching on two inputs and collapsing 8 datasets onto a single cell, with 17 empirical error correlations below the simulated range, and it ignores group size and confidence dispersion. The result warrants the narrow conclusion that a two-parameter summary of the overconfidence account, evaluated on a coarse grid, does not predict dataset-level signs; whether a richer version of the account would fit is open.

## 5. Discussion

Confidence weighting earns a small decision gain and a small judge-prediction loss, and the two do not cancel into a simple verdict. On the preregistered crowd-decision measure, weighting by confidence improved accuracy by about four percentage points of the available margin, and by more on items the crowd did not

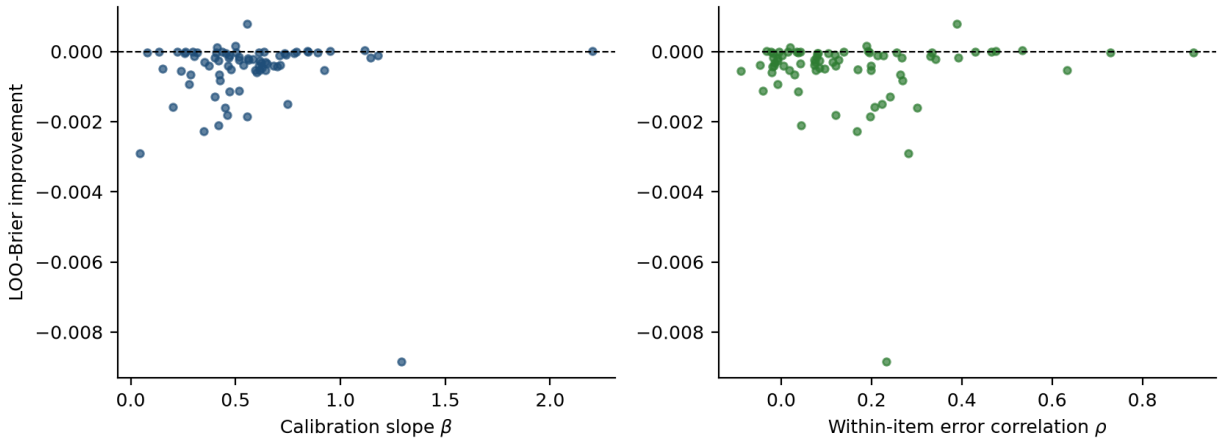

Figure 3: **Figure 4.** Empirical moderation. Left: leave-one-judge-out Brier improvement against the calibration slope. Right: the same against the within-item error correlation. Neither relation is significant, contrary to the theoretical prediction.

already decide; in a held-out item test it reached 0.938 accuracy against 0.926 for equal weighting. On the graded measure, which predicts whether a particular judge is right rather than what the item's truth is, it did slightly worse, by about six ten-thousandths of a Brier point, in 91% of datasets. The two objectives are different, and the theory allows them to disagree when errors are shared: when judges on an item tend to be wrong together, the best predictor of one judge's correctness is close to the item's base rate, which equal weighting estimates well, while the best recovery of the item's truth can still reward sharper weighting.

The simulation shows that the boundary is real in principle. Confidence weighting improved both objectives when confidence was well calibrated, and overconfidence reversed the graded effect and could turn the decision effect negative; across 120 cells the decision gap was negative at some group size in 86, and shrinkage between the two rules was interior in 117. But the data did not follow the predicted moderation. Neither the calibration slope nor the within-item error correlation predicted whether confidence weighting helped, on either measure, and the within-item decomposition of the calibration slope did not change that. The tests had limited power, so this is a failure to detect moderation rather than proof of its absence, but it is not support for the mechanism.

Two results should temper the practical recommendations that would otherwise follow. First, the interior shrinkage optimum is an oracle result. The simulation knew the population parameters and chose the best weight on confidence; in the held-out item test, an estimated shrinkage weight beat equal weighting in only 24% of datasets and never matched the pure confidence-weighted rule. Estimating the shrinkage parameter from the same finite sample reintroduces the estimation noise that motivates shrinking in the first place, so "shrink toward equal weighting" is not a recipe we can recommend from these data. Second, because the calibration slope did not predict the confidence-weighting advantage, an aggregator cannot decide whether to weight by checking the slope on a calibration set. The defensible procedure is to compare the candidate rules directly on held-out items, which is what the held-out test does, and to choose the objective first: confidence weighting is the better bet if the goal is the crowd's decision, equal weighting if the goal is to predict an individual judge's answer.

The model-reproduction failure should be read narrowly. A two-parameter summary of the overconfidence account, snapped to a coarse grid, did not predict dataset-level signs, and on the graded measure it did worse than always predicting a negative effect. That is evidence about this specific, coarse test, not evidence that no account of confidence weighting can work. The ingredients the theory names, calibration and shared error, plausibly still matter; the way we summarised them did not capture what drives the sign in these datasets.

Several limitations bound these conclusions. The corpus was not designed for crowd aggregation. Items are condition cells rather than matched physical stimuli, so judges within a cell may have seen different exemplars, which makes their errors less correlated than the simulation's shared-item and could make confidence informative about a judge's own trial but not about the shared condition; we could not verify how many datasets have a one-to-one stimulus-to-exemplar mapping. The graded measure predicts a held-out judge, not the item's truth. The calibration slope mixes a between-judge and a within-item component, and although a within-item decomposition did not change the conclusions, the pooled estimate remains the wrong coordinate in principle. The meta-analytic summary is an unweighted mean, not a random-effects model. The simulation is one generative model, and its failure to fit is a result about that model. Finally, the graded estimand was added after the preregistered decision estimand proved ceiling-bound, so it is exploratory; the preregistered result, which is favourable to confidence weighting, is reported first throughout.

The findings point to specific next steps. A designed crowd experiment that holds stimuli fixed across judges would remove the item-definition ambiguity and let the decision and judge-prediction objectives be separated cleanly, at group sizes where the theory says the sign turns. A within-item calibration measure estimated with enough precision to test moderation would settle whether calibration governs the weighting advantage. And the divergence between objectives deserves its own study: the conditions under which weighting the crowd by confidence helps the collective decision but hurts the prediction of individual answers are exactly the conditions of shared error that the theory highlights.
